Molecular dynamics combined with the nudged elastic band method reveals the microscopic self-diffusion process of compact silicon tri-interstitials. Tight-binding molecular dynamics paired with ab initio density functional calculations speed the identification of diffusion mechanisms. The diffusion pathway can be visualized as a five defect-atom object both translating and rotating in a screwlike motion along (111) directions. The density functional theory yields a diffusion constant of $4 \times 10^{-5} \exp(-0.49 \text{eV}/k_B T) \text{cm}^2/\text{s}$. The low diffusion barrier of the compact tri-interstitial may be important in the growth of ion-implantation-induced extended interstitial defects.

Which tri-interstitial to study?

In a previous work from our research group,27 the three lowest-energy tri-interstitial geometries, denoted $I_3^a$, $I_3^b$, and $I_3^c$, were identified by analysis of tight-binding molecular dynamics (MD) simulations followed by density functional relaxations. The TB calculations use the Lenosky et al.28 potential. $I_3^a$ is the ground state and $I_3^b$ and $I_3^c$ are excited states;29 the density functional energies for the three defects in $216+3$ atom supercells were $2.24 \text{eV}/\text{atom}$, $2.37 \text{eV}/\text{atom}$, and $2.47 \text{eV}/\text{atom}$, respectively. The tight-binding MD simulations show only $I_3^a$ is a rapid diffuser, while $I_3^b$ and $I_3^c$ can be formed by interconversion of $I_3^b$, but are themselves immobile within the $5 \text{ns}$ time scale of the simulations.27 Hence, we focus on elucidating the microscopic diffusion process of the compact tri-interstitial $I_3^a$, which has a compact defect geometry in which a perfect tetrahedron of four atoms replaces a single atom in the silicon lattice, with the faces oriented along the four symmetry related $\langle 111 \rangle$ directions.

Minimum energy path and/or nudged elastic band

Figures 1(a) and 1(c) show two $I_3^a$ defects in neighboring sites that correspond to initial and final configurations along the diffusion path, the $\langle 111 \rangle$ direction. We obtain the initial pathway from analysis of molecular dynamics trajectories.27

Following high-energy ion implantation, strongly supersaturated silicon self-interstitials can agglomerate to form macroscopic planar interstitial structures, $\{311\}$ defects.$^1$ High-temperature annealing is necessary to remove lattice damage following ion implantation. However, during the annealing process the $\{311\}$ defects comprise a large reservoir of interstitials,$^2$ which are released upon annealing and drive boron transient enhanced diffusion.$^5$–$^7$ an undesirable process which causes spatial broadening of boron concentration profiles. On the other hand, following low-energy implantation, significant boron transient enhanced diffusion (TED) is still observed, even though no visible $\{311\}$ defects are developed.$^7$

It is crucial to understand the diffusion of various point defects in order to have a quantitative understanding of boron TED. Measurements of the diffusion rate of defects in silicon have been reported in experiments.$^8$–$^{14}$ Current experimental techniques cannot cleanly resolve the diffusion rates of more complex defect species, and due to the atomic-scale size of point defects, defect diffusion pathways cannot be resolved at all.$^{15}$ Thus, numerical simulations provide a unique way to study the technologically important dynamics of point defects in silicon.

Previously, such simulations have studied numerous defect species using both classical and quantum Hamiltonians.$^{16}$–$^{20}$ Using nudged elastic band methods$^{21}$ (NEB) within a density functional theory (DFT) code, Lopez et al. compute an activation energy of 0.28 eV for a neutral single interstitial diffusing along the $X$-$T$-$X$ path.$^{22}$ Kim et al. estimates the self-diffusion barrier of a particular di-interstitial performing a reorientation to be 0.5 eV.$^{17}$ Recent DFT-NEB calculations done in our group confirm this pathway but give a somewhat lower barrier of 0.3 eV.$^{23}$

Cogoni et al.$^{24}$ use temperature-accelerated molecular dynamics$^{25}$ with the Kwon et al.$^{26}$ tight-binding (TB) potential to systematically study the diffusion of low-lying single interstitials, di-interstitials, and tri-interstitials. In particular they find all are fast diffusers with diffusion barriers of 0.94, 0.89, and 1.71 eV, respectively. We extend that work both with a more accurate tight-binding potential and with density-functional theory to further refine the diffusion pathway and the diffusion constant. Here we concentrate on the tri-interstitial finding an activation energy of 0.4–0.5 eV in DFT (and 0.6 eV in TB).

Which tri-interstitial to study?

In a previous work from our research group, the three lowest-energy tri-interstitial geometries, denoted $I_3^a$, $I_3^b$, and $I_3^c$, were identified by analysis of tight-binding molecular dynamics (MD) simulations followed by density functional relaxations. The TB calculations use the Lenosky et al. potential. $I_3^a$ is the ground state and $I_3^b$ and $I_3^c$ are excited states; the density functional energies for the three defects in $216+3$ atom supercells were $2.24 \text{eV}/\text{atom}$, $2.37 \text{eV}/\text{atom}$, and $2.47 \text{eV}/\text{atom}$, respectively. The tight-binding MD simulations show only $I_3^a$ is a rapid diffuser, while $I_3^b$ and $I_3^c$ can be formed by interconversion of $I_3^b$, but are themselves immobile within the $5 \text{ns}$ time scale of the simulations. Hence, we focus on elucidating the microscopic diffusion process of the compact tri-interstitial $I_3^a$, which has a compact defect geometry in which a perfect tetrahedron of four atoms replaces a single atom in the silicon lattice, with the faces oriented along the four symmetry related $\langle 111 \rangle$ directions.

Minimum energy path and/or nudged elastic band

Figures 1(a) and 1(c) show two $I_3^a$ defects in neighboring sites that correspond to initial and final configurations along the diffusion path, the $\langle 111 \rangle$ direction. We obtain the initial pathway from analysis of molecular dynamics trajectories.
The climbing-image NEB (CI-NEB) method\textsuperscript{32} refines an accurate pathway and finds the diffusion barrier between these two \( I_x \) minima. The CI-NEB scheme guarantees that the image with the highest energy converges to the saddle point. All NEB calculations are performed with the Vienna Ab-initio Simulation Package (VASP) density functional code\textsuperscript{33,34} employing the Perdew-Wang generalized gradient approximation (GGA)\textsuperscript{35} and ultrasoft Vanderbilt-type pseudopotentials\textsuperscript{36} as provided by Kresse and Hafner.\textsuperscript{37} An initial relaxation of the two end points initiates a full relaxation of seven images along the path, keeping the volume of the cell fixed. Energy and atomic position convergence of \( 3 \) meV and \( 0.005 \) Å, respectively, is confirmed for \( 64+3 \) atom supercell by comparing the results for a \( 250 \) eV energy cutoff and a \( 3 \times 3 \times 3 \) \( k \)-point mesh with a \( 300 \) eV cutoff and a \( 4 \times 4 \times 4 \) mesh. The seven images are initialized by linear interpolation between the two relaxed end points. Each of the images is relaxed until the atomic forces are less than \( 10 \) meV/Å.

Figure 2 shows the diffusion path with an activation energy of \( 0.49 \) eV. Harmonic transition state theory\textsuperscript{34} calculates the defect jump rate \( \Gamma \) from the phonon frequencies at the minimum \( \nu_i^{\text{min}} \) and at the saddle point \( \nu_i^{\text{sad}} \) and the activation energy \( \Delta E \)

\[
\Gamma = \Gamma_0 e^{-\Delta E/k_BT},
\]

where the prefactor \( \Gamma_0 \) is given by

\[
\Gamma_0 = \prod_{i}^{3N-3} \nu_i^{\text{min}} / \prod_{i}^{3N-4} \nu_i^{\text{sad}}.
\]

The dynamical matrix method within \textit{ab initio} GGA density functional theory determines the phonon frequencies. Each atom is displaced in the \( x, y, z \) direction by \( 0.03 \) Å, and the calculated forces are used to construct the Hessian matrix for the system, which is diagonalized to find the phonon frequencies. This yields a jump rate \( \Gamma = 0.2 \) THz \( \text{exp}(-0.49/k_BT) \). Calculations for a larger cell of \( 216+3 \) atoms provide a diffusion barrier of \( 0.43 \) eV estimating a finite size error of about \( 0.1 \) eV.

**Collective motion of atoms**

In the diffusion event, the five most-displaced atoms move collectively, with a screwlike motion. Figures 1(a), 1(b), and 1(c), showing the atomic configurations for initial, saddle, and final states, indicate significant displacement of the five solid colored atoms. All other atoms relax only slightly during the diffusion with a maximum displacement of \( 0.18 \) Å.

In order to illustrate the screwlike collective motion, we highlight the five highly displaced atoms in Fig. 3. Atoms \( A, B, \) and \( C \) are located in a \( 111 \) plane, forming an equilateral triangle, and translate along and rotate, clockwise or counterclockwise, about the \( [111] \) axis defined by atoms \( D \) and \( E \). Meanwhile, atoms \( D \) and \( E \) translate along the same \( [111] \) direction. Atoms \( D, A, \) and \( B \) form an equilateral triangle, whose normal vector indicates another diffusion direction, and all five atoms form a double tetrahedron. The bond between \( A \) and \( B \) is \( 2.49 \) Å at the minimum, \( 6\% \) longer than the perfect silicon-silicon bulk bond distance. During the diffu-

**FIG. 1.** (Color online) Diffusion of \( I_x \) to the neighboring site along the \( \langle111\rangle \) direction. The initial, saddle, and final configurations are shown in (a), (b), and (c), respectively. Defect atoms are solid colored. The figures with more atoms can be found in Ref. 31.

The diffusion event this bond length varies by less than 4.5%. During defect migration the double-tetrahedron translates 1.31 Å and rotates 60° as shown in Fig. 1. Table I lists the values for the translation and rotation of the seven relaxed NEB images.

The diffusion event is approximated by a uniform translation and rotation of a fixed double tetrahedron. For instance, rotating the double tetrahedron of the initial configuration (image 1) by 16.4°, and translating it by 0.57 Å while keeping its geometry fixed and relaxing the other atoms provides an approximation to image 3. Applying this procedure to each of the images along the diffusion path, we obtain the approximate path in Fig. 2. The approximate activation energy is 0.6 eV, only 20% higher than the fully relaxed value.

Figure 4 shows the translation and rotation of the double tetrahedron during the diffusion. Translation occurs before the structure rotates. The double tetrahedron is displaced half way and rotated 30° at the saddle point. The insets show images 3, 5 (saddle point) and 7 viewed from the [111] direction and illustrate that threefold symmetry persists during the diffusion.

TABLE II. Formation and activation energy of the neutral single-interstitial diffusing along the X-Y-X path, and of the neutral ground state di-interstitial and compact tri-interstitial during self-diffusion. The formation energies are calculated in a 216+n atom supercell and the activation energies are calculated using NEB with a 64+n atom supercell. Details of the diffusion paths of single interstitials and di-interstitials will be published elsewhere (Ref. 23).

NEB result from Ref. 22 is calculated using 216+1 atom supercell.

**Diffusion rate**

The defect I₃ can move to four neighboring sites along the four symmetry equivalent (111) directions. The diffusion constant of this random walk is \(D = \frac{2}{3} \alpha \Gamma T\), where the jump rate \(\Gamma\) is defined by Eq. (1) and the displacement during the diffusion event is \(a = 1.31\) Å. The resulting diffusion constant is \(D = 4 \times 10^{-3} \exp(-0.49 \text{ eV}/k_BT) \text{ cm}^2/\text{s}\).

**Discussion**

Table II summarizes the \(ab\ initio\) density functional theory results for formation and activation energy of I₁, I₂, and compact I₃ defects. The theoretical values of 0.28–0.49 eV are considerably lower than the experimental results from metal-diffusion experiments which find activation energies, believed to be for single interstitials, typically ranging from ~1.4 to 1.8 eV. However, a recent experiment identifies enhanced diffusion of single interstitials at 150 K, while noting it is inconsistent with results from earlier approaches. This lower temperature would be consistent with the NEB result for the energy barrier of single interstitial diffusion of 0.3 eV.

Our pathway for I₃ diffusion is the same as that found by Cogoni et al. in the 64+3 atom supercell. On the other hand, our DFT barriers for I₁, I₂, and I₃ of 0.3, 0.3, and 0.4–0.5 eV are much smaller than the tight-binding results by Cogoni et al. of 0.9, 0.9, and 1.7 eV. To understand the differences in the energy barriers between Cogoni’s and our results, we calculate the diffusion path for I₃ with Kwon’s TB potential using \(\Gamma\) point and obtain a diffusion barrier of 1.2 eV in contrast to the 0.6 eV barrier with Lenosky’s TB potential. We further check the k-point convergence using up to a 4^3 mesh for both TB models. The converged diffusion barriers are 0.9 eV and 0.6 eV for Kwon’s and Lenosky’s TB potential, respectively. This indicates that the larger energy barriers of Cogoni et al. are due to the difference in the TB potential and insufficient k-point convergence.

We perform density of states (DOS) calculations for the interstitial defect along the diffusion path within a 216+3 atom supercell. The DOS is calculated for the minimum, the
saddle point, and an intermediate structure. The DOS shows a band gap of 0.71–0.74 eV for all three configurations along the diffusion pathway with no states in the gap.\(^{31}\) The size of the gap is close to the band gap of pure Si in GGA of 0.72 eV. The lack of gap states indicates that charge transfer may not play a significant role for the diffusion of a compact tri-interstitial.

While the formation energy of \(I_3\) is lower than \(I_1\) on a per atom basis, it is much higher when considered on a total basis (see Table II). One implication that can be drawn from this is that under equilibrium conditions, \(I_3\) is not present in any significant quantity, but under conditions which inject excess interstitials,\(^{32}\) such as ion implantation, it may be present in significant amounts due to the combination of mobile single interstitials. Our results have possible relevance for modeling transient enhanced diffusion which follows ion implantation.\(^{42}\)

**Conclusions**

We have elucidated the pathway for the diffusion of the compact tri-interstitial \(I_3\), the only fast diffusing tri-interstitial species in crystalline silicon. During the self-diffusion event, five atoms move collectively in a screwlike motion along one of four symmetry-related \((111)\) directions. Our DFT result shows a low activation energy of 0.49 eV and a diffusion constant of \(4 \times 10^{-5} \exp(-0.49 eV/k_B T)\) cm\(^2\)/s. Under conditions such as ion implantation that creates excess interstitials and hence favor cluster formation, \(I_3\) diffusion may be an important process due to the low activation energy.
